Supporting Information

ABSTRACT: Cell-free metabolic engineering (CFME) is advancing a powerful paradigm for accelerating the design and synthesis of biosynthetic pathways. However, as most cell-free biomolecule synthesis systems to date use purified enzymes, energy and cofactor balance can be limiting. To address this challenge, we report a new CFME framework for building biosynthetic pathways by mixing multiple crude lysates, or extracts. In our modular approach, cell-free lysates, each selectively enriched with an overexpressed enzyme, are generated in parallel and then combinatorically mixed to construct a full biosynthetic pathway. Endogenous enzymes in the cell-free extract fuel high-level energy and cofactor regeneration.

As a model, we apply our framework to synthesize mevalonate, an intermediate in isoprenoid synthesis. We use our approach to rapidly screen enzyme variants, optimize enzyme ratios, and explore cofactor landscapes for improving pathway performance. Further, we show that genomic deletions in the source strain redirect metabolic flux in resultant lysates. In an optimized system, mevalonate was synthesized at 17.6 g·L⁻¹ (119 mM) over 20 h, resulting in a volumetric productivity of 0.88 g·L⁻¹·hr⁻¹. We also demonstrate that this system can be lyophilized and retain biosynthesis capability. Our system catalyzes ~1250 turnover events for the cofactor NAD⁺ and demonstrates the ability to rapidly prototype and debug enzymatic pathways *in vitro* for compelling metabolic engineering and synthetic biology applications.

KEYWORDS: cell-free metabolic engineering, metabolic pathway debugging, cell-free synthetic biology, mevalonate, *Escherichia coli*, *in vitro*

Isoprenoids are a promising class of metabolic engineering targets with over 40 000 known structures and potential uses as pharmaceuticals, flavors, fragrances, pesticides, disinfectants, and chemical feedstocks.^{1,2} Already, the field has demonstrated heterologous production of the antimalarial drug artemisinin,³ the anticancer compound intermediate taxadiene,⁴ the rubber-precursor isoprene,⁵ the ginkgolide-precursor levopimaradiene,⁶ the commodity chemical limonene,⁷ the biofuel 3-methyl-3-buten-1-ol,⁸ and many other plant secondary metabolites.^{9,10}

While the number¹¹ and impact^{12–14} of industrial-scale metabolic engineering processes are increasing, engineering biosynthetic pathways within cells remains subject to several constraints. First, delicate flux balancing and promoter tuning can be time-consuming.^{4,15–17} In one example, the semi-synthetic artemisinin endeavor required over 150 person-years of work, mostly for “pathway balancing”.¹² Second, cell viability is often limited by the high concentrations of intermediate metabolites or final products.¹⁸ A specific challenge for isoprenoid production using the mevalonate pathway (Figure 1A) is the buildup of the toxic intermediate hydroxymethylglutaryl (HMG)-CoA.^{19,20} Finally, competition between the

cell’s physiological and evolutionary objectives (growth) and the engineer’s process objectives (target production) can result in low volumetric productivities (g·L⁻¹·hr⁻¹) and byproduct losses through competing pathways.²¹ Due to these constraints, new prototyping tools and biomanufacturing strategies are needed to alleviate long development times and facilitate faster pathway optimization.²²

In recent years, cell-free metabolic engineering (CFME) has emerged as a new approach to prototype pathway performance and expand the paradigm of traditional biomanufacturing.^{21–26} CFME employs *in vitro* ensembles of catalytic proteins for the production of target products.²² Cell-free systems permit easy manipulation of reaction conditions, avoid possible toxicity constraints, and theoretically allow all carbon/energy resources to be directed to product formation. While purified enzyme systems offer exquisite control of reaction components,^{27–30} crude lysates contain highly active and complex metabolic networks without the need for purification. The ability of crude

Figure 1. A cell-free metabolic engineering (CFME) framework for pathway prototyping demonstrated with the mevalonate pathway. (A) Enzymatic route for isoprenoid synthesis *via* the mevalonate pathway. Acetyl-CoA acetyltransferase (ACAT, green square), hydroxymethylglutaryl-CoA synthase (HMGS, blue star), and hydroxymethylglutaryl-CoA reductase (HMGR, multi-colored circle) are selectively overexpressed in *E. coli* prior to cell lysis and extract preparation. (B) Cell-free metabolic engineering approach. *E. coli* containing overexpressed enzymes of the mevalonate pathway are lysed and centrifuged to make multiple distinct crude extracts. Mixing of extracts allows testing of enzyme variants and optimization of enzyme ratios; subsequently, cofactors such as ATP, NAD⁺, and CoA can be optimized and genomic modifications made to the source strain. (C) Pathway balancing. Three glucose can be converted to two mevalonate assuming nonpathway enzymes in the lysate convert 6 excess ATP and 8 excess NADH to ADP and NAD⁺, respectively.

extracts to recycle energy and cofactors highlights a key advantage of lysate-based CFME. For example, previous demonstrations of crude lysate CFME for production of dihydroxyacetone phosphate (DHAP) derivatives,³¹ ethanol,³² and 2,3-butanediol³³ highlight long (>8 enzyme) pathways with high cofactor turnover. However, these examples all used lysates created from a single source strain containing the entire metabolic pathway.

Here we propose a new approach for crude extract-based CFME. Specifically, we sought to reconceptualize the “build” step of design-build-test loops by advancing a modular approach to making molecules using cell-free cocktails containing multiple lysates (or extracts). The key idea is that each enzyme in the candidate pathway is overexpressed in its own source strain, from which an extract is prepared. Then, the extracts are mixed in multiple, different ratios to assemble the pathway and provide initial insights into beneficial enzyme ratios, promiscuity to different starting substrates, and possible side reactions. This work builds on efforts by Liu *et al.* to prototype fatty acid biosynthesis using a single lysate plus purified enzymes,³⁴ however, in our approach the enzymes are not purified. We validated this concept by prototyping a system for conversion of glucose to mevalonate, an intermediate in isoprenoid synthesis (Figure 1B).

We show that our method provides flexibility for rapidly testing enzyme variants, manipulating physicochemical conditions, and assessing genomic modifications on pathway

performance. We expect the methods reported here to provide a discovery-centered strategy for assessing biosynthetic pathway in a system that (i) mimics the cytoplasmic environment, (ii) permits design-build-test (DBT) iterations without the need to reengineer organisms, and (iii) explores combinatorial and modular assembly of pathways through the use of well-defined experimental conditions. As previous publications have shown that enzymes selected for *in vitro* activity subsequently perform well in the cell,^{34–39} our approach may aid in the development of enzyme pathways and circuits^{40–42} for metabolic engineering and synthetic biology applications. Our work may also advance interest in using CFME systems for biomanufacturing.²²

RESULTS AND DISCUSSION

Construction of a Cell-Free Platform for Mevalonate Production. To demonstrate our new framework for CFME, we selected the mevalonate synthesis pathway.⁴³ The goal was to reconstruct mevalonate biosynthesis *in vitro* by mixing and matching selectively enriched lysates in cell-free cocktails. Endogenous enzymes for central metabolism in the lysate would catalyze the native glycolytic cascade from glucose to acetyl-CoA, which was coupled with three overexpressed enzymes to convert acetyl-CoA to mevalonate (Figure 1A). Previous efforts have shown that *E. coli* crude extracts have highly active central metabolism⁴⁴ and are able to rapidly metabolize glucose to pyruvate, acetyl-CoA, and other glycolytic intermediates.^{31,33}

To enable cell-free biosynthesis of mevalonate, we first introduced individual genes into the source strain BL21(DE3). These genes encode one of three enzymes needed to convert acetyl-CoA to mevalonate (see Table 1 for Strains and Plasmids and Appendix S1 for gene sequences). The three enzymes and their functions are described here. First, acetyl-CoA acetyltransferase (ACAT) catalyzes a Claisen condensation of two acetyl-CoA molecules to acetoacetyl-CoA. Second, hydroxymethylglutaryl-CoA synthase (HMGS) mediates the condensation of acetyl-CoA with acetoacetyl-CoA to generate 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA). Third, hydroxymethylglutaryl-CoA reductase (HMGR) facilitates a four-electron oxidoreduction of HMG-CoA to mevalonate requiring two NADPH or two NADH.⁴⁵ Separate crude lysates of *E. coli* BL21(DE3), each overexpressing a single pathway enzyme (ACAT, HMGS, or HMGR), were prepared. On the basis of our previous work,³³ we used strong, tightly controlled promoters and strong ribosome binding sites for plasmids harboring the enzymes. In contrast to other metabolic engineering efforts, our approach does not require the focus on flux balancing and delicate promoter tuning to maintain viability as for *in vivo* systems.^{4,15–17} Our goal is to maximally express proteins *in vivo*, then mix-and-match corresponding lysates to optimize cell-free production (without viability^{19,20} and growth constraints of cells). As expected, we observed that the heterologous proteins were overexpressed as the dominant bands on an SDS-PAGE gel of the extracts (Figure S1).

After lysis and extract preparation, we reconstituted the pathway from glucose to mevalonate by mixing three separate extracts containing an overexpressed enzyme (ACAT, HMGS, or HMGR) with salts and substrates to initiate the cell-free biosynthesis reaction. The CFME reaction contains extract, substrate (glucose), catalytic amounts of cofactors (1 mM NAD⁺ and 1 mM CoA), 1 mM ATP, and acetate salts to mimic the cytoplasmic environment. In addition, phosphate was supplemented (10 mM) in a manner consistent with previous

work where cell-free protein synthesis was energized from glucose and G6P.⁴⁶ Cation concentrations (Mg²⁺, NH₄⁺, and K⁺) were based on our previous work³³ and are consistent with principles of cytoplasmic mimicry.^{44,47} Initially, glutamate was used as the counterion for magnesium, potassium, and ammonium salts.⁴⁷ However, acetate salts were found to achieve higher mevalonate titers (Figure S2) and were subsequently used for the remainder of the study.

Our initial analysis used heterologous HMGS and HMGR sequences from *Saccharomyces cerevisiae*, as described by Dueber and co-workers.⁴³ Upon incubation with essential substrates, we assessed mevalonate synthesis in 25 μL CFME batch reactions carried out for 24 h at 37 °C *via* gas chromatography mass spectroscopy (GC-MS) (Figure 2A). After 9 h, 12.8 ± 1.3 mM of mevalonate (~1.6 g·L⁻¹) was generated at a linear productivity of 1.43 ± 0.15 g·L⁻¹·hr⁻¹ (Figure 2B). NAD(P)H and ATP are not limiting in this cell-free reaction since the extract contains enzymes that convert glucose to NAD(P)H and microsome vesicles that produce ATP from proton motive force.⁴⁴

Evaluation of Enzyme Variants for Mevalonate Production. Following demonstration of active mevalonate synthesis with our CFME approach, we leveraged extract mixing to modularly identify best performing enzyme homologues (Table 1) as well as evaluate differences in cofactor specificity (NADH *vs* NADPH). We first tested NADPH-preferring HMGRs from three different organisms: *S. cerevisiae*, *Enterococcus faecalis*, and *Staphylococcus aureus*. In 24-h CFME reactions with 200 mM glucose (with or without 1 mM NADP⁺ supplementation), we observed mevalonate titers ranging from 3.7 to 70.9 mM (Figure 2B). The Type I HMGR from eukaryotic *S. cerevisiae* exclusively uses NADPH and produces the lowest mevalonate titer. However, it is a truncated enzyme containing only the catalytic domain, which may affect its stability and/or catalytic activity. Unique for a Type II HMGR, the *E. faecalis* version is also NADPH-dependent⁵¹ and

Figure 2. Synthesis of mevalonate from glucose *via* mixing of three BL21(DE3) extracts each containing a single overexpressed pathway enzyme (ACAT, HMGS, or HMGR), plus native glycolysis enzymes (A). Enzyme variant prototyping identified active NADPH-preferring HMGRs (B), but demonstrated that NADH-dependent reductases (C) produced a higher mevalonate titer. Each extract contributed $3.3 \text{ mg}\cdot\text{mL}^{-1}$ of total protein to the reaction. The system containing ACAT from *E. coli*, HMGS from *S. cerevisiae*, and HMGR from *P. mevalonii* was selected for future characterization. Values represent averages ($n = 3$) and error bars represent 1 s.d.

is a bifunctional enzyme fused to ACAT. The *E. faecalis* HMGR increased mevalonate titer 3-fold over the yeast HMGR. Finally, we found the Type II HMGR from *S. aureus* to be the most active homologue, perhaps because it is able to utilize both NADH and NADPH despite NADPH being its preferred cofactor.⁵² Validating our method for identifying active sets of enzymes through our mix-and-match approach, the HMGR from *S. aureus* has been previously identified as outperforming the variant from *S. cerevisiae*.⁴⁸

In contrast to the abbreviated metabolic pathway depicted in Figure 1A, the activity of NADPH-dependent HMGRs (Figure 2B) demonstrates generation of NADPH by the cell-free system. Two sources of NADPH are most likely: First, oxidation of glucose through the pentose phosphate pathway generates NADPH catalyzed by glucose-6-phosphate dehydrogenase (*zwf*) and 6-phosphogluconate dehydrogenase (*gnd*). Alternatively, soluble (*sthA*) or membrane-bound (*PntBA*) transhydrogenase enzymes present in the extract may be generating NADPH and NAD⁺ from substrates NADH and NADP⁺. In effort to provide additional NADPH to the system, we added transhydrogenase (*sthA*)-enriched extract to the reaction, but did not observe an increase mevalonate titer (Figure S3).

To extend our analysis, we considered NADH-dependent Type II HMGRs. In our experiments, these enzymes generated the highest mevalonate titers (Figure 2C), particularly those from *Pseudomonas mevalonii* and *Bordetella petrii*. This is consistent with the expectation that Embden–Meyerhof–Parnas glycolysis described in Figure 1A generates NADH reducing equivalents which are directly available for reducing HMG-CoA to mevalonate. Compared to our base case (*S. cerevisiae* HMGR: $12.8 \pm 1.3 \text{ mM}$ over 9 h), titers are ~6-fold higher for the *P. mevalonii* HMGR ($84.2 \pm 8.1 \text{ mM}$ over 15 h). Variation of the second enzyme (HMGS) increased the rate of synthesis slightly; however, the *S. cerevisiae* homologue gives the highest final titer (Figure 2C). The mixing-and-matching of lysates informed the selection of ACAT from *E. coli*, HMGS from *S. cerevisiae*, and HMGR from *P. mevalonii* for further characterization.

Testing of Enzyme Ratios and Guided Construction of an All-in-One Source Strain. A key conceptual shift of our approach is that the design element is a lysate rather than a gene. Once in hand, selectively enriched lysates can be mixed in

different ratios to assemble new pathways, estimate beneficial enzyme proportions, and determine which enzymes might be rate-limiting (Figure 3A). In this work, extract ratios were calculated as a fraction of total protein mass ($\text{mg}\cdot\text{mL}^{-1}$) in the CFME reaction (each reaction contained $10 \text{ mg}\cdot\text{mL}^{-1}$ total protein). Notably, each enzyme was overexpressed to similar levels in the lysate (Figure 3B). We observed that overall mevalonate yields from glucose were relatively insensitive to different extract ratios.

We next set out to construct an all-in-one extract from a source strain overexpressing all three pathway enzymes, as we had previously reported on for the production of 2,3-butanediol.³³ To do this, we needed to clone the entire pathway for mevalonate onto a single plasmid using design rules for enzyme sets and pathway ratios above. It is well-known that genes positioned earlier in an operon have a higher relative expression level.⁵³ Since higher ratios of HMGR and HMGS may be better (Figure 3A), HMGR and HMGS were placed first on the plasmid, followed by ACAT (Table 1). After lysate preparation, SDS-PAGE confirmed that the single strain expresses all three proteins at similar levels to the individually mixed condition (Figure 3B).

We next compared mevalonate production between our all-in-one and mix-and-match systems in a 28 h CFME reaction. The all-in-one extract system performs similarly to three extracts mixed at equal ratios (Figure 3C). We observed that pH decreases over the course of reaction in both systems, possibly due to an increase in dissolved carbon dioxide from pyruvate decarboxylation.⁵⁴ Upon testing a number of buffers, we found 100 mM and 200 mM Bis-Tris to successfully stabilize reaction pH closer to 7.0 and produce the same titer of mevalonate.

One important consideration in CFME is the desire to have the same amount of soluble heterologously expressed protein in the extract when comparing enzyme homologues. While most overexpressed enzymes have some portion that is insoluble (Figure S4A), extract preparation removes insoluble proteins and cellular debris. Thus, solubility of a homologue does not obscure its apparent activity. However, apparent activity could be impacted by the percentage of soluble overexpressed enzyme in each extract relative to the total *E. coli* protein (in our experiments this varied from approximately 4% to 24% of the total protein content of the extract; Figure S4A). Since

Figure 3. Modulating extract ratios informs construction of an all-in-one extract. (A) Varying the mass ratio of the three extracts demonstrates expression of pathway enzymes is not rate-limiting to the system. (B) SDS-PAGE gel (Coomassie stain) shows: overexpression of three pathway enzymes in a single extract, individual enzyme-enriched extracts mixed together in a CFME reaction, and individual enzyme-enriched extracts. (C) The single BL21(DE3) extract with all three pathway enzymes overexpressed performs similarly to three extracts mixed at equal ratios (Insert) Enzymes are active though pH decreases over the course of reaction. Addition of buffers stabilizes the pH but does not affect mevalonate yield. Values represent averages ($n = 2$ for A, $n = 3$ for C) and error bars represent 1 s.d.

altering the ratio of each extract has a small effect on overall mevalonate titer (Figure 3A), we suspect that overexpressed enzyme concentration is not limiting in our experiments. This conclusion is supported by our recent work in using lysates to synthesize 2,3-butanediol where heterologous pathway flux is limited by glycolysis.³³ While we find little to no correlation between mevalonate titer and recombinant protein expression level (Figure S4B), we acknowledge that enzyme overexpression is a potential source of variation that could be controlled for using a normalization step.⁵⁵ Another consideration for CFME is that proteins which express poorly may not be good candidates for this prototyping approach. Finally, we highlight that the toxicity pressure of some intermediates, such as HMG CoA,^{19,20} may not be accurately captured in the CFME prototyping strategy, representing a potential shortcoming.

Optimization of Cofactors. An important consideration in cell-free systems is the concentrations of salts and cofactors. Indeed, it has been shown that ionic compositions and reaction conditions that closely reflect the cytoplasm are beneficial for activating multiple metabolic and energy regeneration pathways.^{44,47,56,57} To provide an example of CFME's prototyping capabilities, we studied the impact of initial cofactor ratios on mevalonate synthesis. CFME reactions were carried out for 24 h in which the supplemental cofactors NAD^+ , ATP, and CoA were removed one-by-one, in pairs, and altogether (Figure 4A). This revealed NAD^+ to be critical to high mevalonate titer; its absence reduced mevalonate concentration by over half. Relatively high mevalonate titers were maintained without

supplementation of ATP (required for the pay-in phase of glycolysis) and CoA (a cofactor for the pyruvate dehydrogenase complex converting pyruvate to acetyl-CoA).

Surprisingly, glucose, acetate salts, phosphate, and extract can support ~80% of yield without any supplementary cofactors (Figure 4A: red bar). These results suggest that intracellular cofactors (such as NAD^+ , ATP, and CoA) are carried over from the cytoplasm into the extract during extract preparation and are at sufficient concentration to drive mevalonate synthesis. To verify this hypothesis, we directly measured the NAD^+ concentration in the cell-free reaction without supplementation. We found the NAD^+ concentration to be 0.09 ± 0.035 mM (Figure S5). Each conversion of HMG-CoA to mevalonate requires two reducing equivalents; thus, the system with 1 mM NAD^+ supplementation has ~200 turnover events while the system without supplementation has ~1250. These values are 2 orders of magnitude higher than typical turnover values of purified CFME systems (5–20 turnover events),²² and are similar to those of state-of-the-art crude extract systems.^{32,33} While the main goal of our study was to develop a new CFME framework for modularly prototyping enzyme homologues and reaction conditions, the possibility of achieving high titers without costly cofactor supplementation is important if one envisions using CFME for industrial applications.

Direct access to the cell-free reaction increases the resolution at which biochemical conditions can be manipulated compared to living systems. We therefore sought to further explore concentration-dependent effects of NAD^+ , ATP, and CoA in the CFME reaction. Specifically, we modulated concentrations

Figure 4. The presence and concentration of cofactors modulates mevalonate yield. (A) Cofactors NAD⁺, ATP, and CoA were supplemented to the reaction two-at-a-time, one-at-a-time, and not supplemented at all. Glucose, acetate salts, phosphate, and extract can support ~80% of yield with no supplementary cofactors (red bar). Variation of initial ATP and NAD⁺ concentration with no CoA (B) and 1 mM CoA (C) modulates final mevalonate concentration at 20 h. The black bar in (A) and (C) represents the cofactor concentration (1 mM ATP, 1 mM NAD⁺, 1 mM CoA) used in all other figures. Values represent averages ($n = 3$) and error bars represent 1 s.d.

from 0 to 1 to 10 mM for NAD⁺ and ATP at two different CoA concentrations (0 and 1 mM) (Figure 4B and 4C). The two landscapes offer different trends with no obvious shared pattern, indicating a complex interplay between cofactor concentrations, extract components and resulting metabolic fluxes. Interestingly, our initial choice of concentrations (1 mM each) proved to generate a nearly equivalent mevalonate titer compared to the best condition (Figure 4C).

Source Strain Genome Engineering to Redirect Metabolic Flux: Knockout of *ldhA*, *acs*, and *ackA-ptA*. Knockout of competing metabolic pathways is a common strategy in metabolic engineering to increase product titer.¹³ As crude lysates contain many other endogenous enzymes in addition to our desired pathway enzymes (Figure 5A), it is possible that competing pathways siphon carbon flux from mevalonate biosynthesis (Figure 5B). We therefore studied our CFME reactions by monitoring small molecule organic acid concentrations at selected time points in batch reactions using high performance liquid chromatography (HPLC). Quantification revealed that lactate (Figure 5C), and pyruvate (Figure 5D) accumulate while glucose (Figure 5E) and acetate (Figure 5F) concentrations decrease over the course of the reaction. Phosphate, ethanol, oxaloacetate concentrations remained constant (Figure 5G).

To elucidate the role of lactate and acetate metabolism, knockout mutations were made in the source strain prior to extract preparation using the Datsenko–Wanner technique⁵⁸

(Figure 5A). The idea of modifying extract source strains is not new in cell-free synthetic biology and has been used for enhancing cell-free protein synthesis systems,^{59,60} however, source strain gene knockouts have been underutilized in the cell-free metabolic engineering context with only one other known example to date.³¹

To prevent lactate accumulation, we deleted the *ldhA* gene (encoding lactate dehydrogenase) in the extract source strain. The knockout was confirmed by PCR (Figure S7) and by sequencing (see Appendix S2). After generating extract with mevalonate pathway genes, we carried out a 24 h CFME reaction. Mevalonate synthesis rates and titers were halved as compared to the control (extract containing *ldhA*). Glucose and acetate consumption rates are consistent with wild type for the first 6 h; after this, however, the consumption rates slow. We hypothesize that the decrease in mevalonate titer is because lactate dehydrogenase is no longer available to recycle excess NADH to NAD⁺. This cofactor recycle is necessary because the enzymatic pathway is not cofactor balanced (Figure 1C). Without lactate dehydrogenase, a low amount of succinate accumulates, presumably due to the TCA cycle fixing acetyl-CoA and consuming NADH to make succinate (Figure S6). Although lactate accumulation diverts carbon flow from mevalonate, it appears that nonlactate sinks for excess NADH are saturated after 6 h, ultimately limiting mevalonate titer.

To understand the impact of acetate metabolism on mevalonate synthesis, we made a series of mutant extract

Figure 5. Source strain genome engineering can redirect metabolic flux in the cell free reaction. (A) Simplified metabolic pathway with target enzymes for knockout in color. (B–G) Concentrations of metabolites over time within a cell free reaction: (B) Mevalonate (C) Lactate (D) Pyruvate (E) Glucose (F) Acetate (G) pH. Knockout of *ldhA* eliminates lactate accumulation and knockout of *ackA-pta* eliminates acetate consumption. Acetate consumption is hypothesized to be a necessary sink for excess ATP generated by the glycolysis phase of the pathway. Values represent averages ($n = 3$) and error bars represent 1 s.d.

source strains. Acetate catabolism in *E. coli* occurs via the *acs* enzyme or the *ackA-pta* pathway, both of which require ATP (Figure 5A). Unlike the wild type system, the concentration of acetate in $\Delta\textit{ackA-pta}$ and $\Delta\textit{acs}\Delta\textit{ackA-pta}$ extracts remained constant at 200 mM (Figure 5F); this indicates that acetate kinase (*ackA*) and phosphate acetyltransferase (*pta*) are active in the wild type scenario. Without these enzymes, mevalonate synthesis was reduced to ~ 5 mM and much less glucose was consumed (70 mM) compared to the wild type system (180 mM). In contrast, the acetyl-CoA synthase knockout ($\Delta\textit{acs}$) performed identical to wild type. These results suggest that *ackA* and *pta* are converting acetate to acetyl-CoA, which is subsequently available as a substrate for incorporation into mevalonate (Figure 5A). This may explain the improvement in mevalonate titers when using acetate salts compared to glutamate or chloride salts (Figure S2). Since knockout of *ackA* and *pta* are deleterious to mevalonate titers, we hypothesize that these enzymes may be important in converting excess ATP from glycolysis to ADP; however, further experimentation would be needed to assess this.

Evaluation of Freeze-Dried Extracts for Distributed Biomanufacturing. High-level cofactor regeneration is an important first step for prospective cell-free biomanufacturing applications using crude extracts.²² Such extract-based systems may offer opportunities for decentralized production, especially given recent works with freeze-dried components that do not require cold storage. Recently, Bundy and colleagues used lyophilized extracts to make the therapeutic protein onconase⁶¹ as well as other proteins.^{62,63} Additionally, Collins and co-workers have pioneered paper-based, colorimetric diagnostics using toehold switches and freeze-dried cell-free transcription

and translation systems to detect Ebola⁶⁴ and Zika⁶⁵ viral RNA. Here, we freeze-dried the complete CFME system containing the lysate with selectively enriched pathway enzymes, substrates, cofactors, and salts. By rehydrating the system, we observed similar mevalonate synthesis rates and titers when compared to the non freeze-dried system (Figure 6).

Summary. To our knowledge, this work is the first demonstration of mixing multiple selectively enriched crude extracts to reconstitute a metabolic pathway. Specifically, we showed the ability to reconstitute the pathway from glucose to mevalonate by mixing three enzyme-enriched lysates. We improved mevalonate titer at 15 h from our initial case of 1.6 g-

Figure 6. Lyophilization of cell-free reactions for mevalonate production. Complete CFME reactions containing the enzyme-enriched lysate, substrates, cofactors and salts were assembled, immediately flash-frozen, and lyophilized. The rehydrated CFME reactions were directly compared to a standard nonlyophilized CFME reaction. Values represent averages ($n = 3$) and error bars represent 1 s.d.

L⁻¹ (12.8 mM) to 12.5 g·L⁻¹ (84.2 mM) by prototyping enzyme homologues (Figure 2B,C). After developing an all-in-one source strain with optimization of small molecule cofactors, the titer increased to 17.6 g·L⁻¹ (119 mM) over 20 h; this titer correlates to a productivity of 0.88 g·L⁻¹·hr⁻¹ (Figure 4C). Using the *ackA-pta* pathway to metabolize acetate as a carbon source in addition to glucose (Figure 5), the overall carbon yield is estimated to be 0.35 mol carbon product/mol carbon substrate (when accounting for CO₂ lost, the stoichiometric maximum is 0.75 mol product/mol substrate) (Appendix S3). This is 46.9% of theoretical yield. Turnover of the cofactor NAD⁺ was ~1250 when not supplemented. This value is higher than most purified enzyme systems²² and similar to two other recent publications.^{32,33} The ability of crude extract native metabolism to recycle excess ATP and NADH highlights a potential advantage of lysate-based CFME. Of note, our work complements efforts by several groups to prototype isoprenoid synthesis using purified enzymes^{37,66–68} as well as *in vivo* metabolic engineering efforts (Table S1).^{43,69–71}

Within cell-free synthetic systems, there is growing interest to prototype pathway performance,^{34–42} such as a recent report that demonstrates mixing of purified enzymes with a crude extract in a glucose-to-hydrogen enzyme pathway⁷² and another exploring fatty acid biosynthesis.³⁴ As a prototyping platform, testing of new enzyme variants by CFME requires only purchasing the gene, one-step cloning into an expression vector, preparing extract, and running a cell-free reaction. In a parallel effort, we extended the concept here to include cell-free protein synthesis, where lysates are selectively enriched, not by heterologous expression, but by producing the pathway enzymes directly from linear PCR templates in cell-free protein synthesis reactions.⁷³ This approach accelerates the timeline of prototyping and could be leveraged to express and evaluate membrane proteins.⁷⁴

In summary, our work demonstrates the high activity of CFME extracts and outlines an extract mixing approach allows easy screening of enzyme variants. Looking forward, we expect that our approach will complement existing strategies for gene discovery and pathway prototyping by changing the focus of the biosynthesis “unit operation” from the cell to the lysate, enabling the use of multiple organisms with or without additional genetic engineering.

MATERIALS AND METHODS

Strains and Plasmids. All strains and plasmids for this study are listed in Table 1. Mevalonate pathway genes from *E. coli* (ACAT) and *S. cerevisiae* (HMGS/HMGR) were obtained from pGW322,⁴³ kindly provided by Jay Keasling. Sequences were PCR-amplified using Phusion polymerase and primers which contained appropriate *EcoRI*, *BglII*, *BamHI*, and *XhoI* restriction sites used by the Berkeley Cloning Standard (BCS).⁷⁵ The remaining HMGS and HMGR amino acid sequences were obtained from the Universal Protein Resource (UniProt), codon optimized for expression in *E. coli*, and synthesized (with flanking BCS restriction sites) by Gen9 (Cambridge, MA) or Integrated DNA Technologies (Coralville, IA). Ribosome binding site (RBS) sequences were designed and optimized to be greater than 30 000 arbitrary units using the Salis RBS calculator (v1.1).⁷⁶ Sequences are available in the supplement (Appendix S1).

Gene sequences were digested and ligated into pETBCS, a modified pET-22b vector (Novagen/EMD Millipore, Darmstadt, Germany) with signal sequence removed and modified

restriction sites.³³ Routine cloning was performed using the *E. coli* strain NEB Turbo and all DNA-modifying enzymes were purchased from NEB (New England BioLabs, Ipswich, MA).

BL21(DE3) (purchased from Invitrogen/Thermo Fisher Scientific, Waltham, MA) was used as the source strain for extract production. Knockout strains were generated using the Datsenko-Wanner technique,⁵⁸ where the complete gene coding sequence (from start to stop codon) was replaced by a noncoding “scar” sequence containing the FRT recognition sequence. Sequences are available in the supplement (Appendix S2).

Cell Growth and Extract Preparation. *E. coli* containing the appropriate pETBCS-based plasmid (harboring one or more pathway genes) were grown in 1-L Tunair shake flasks at 37 °C (250 rpm) in rich media (18 g·L⁻¹ glucose, 16 g·L⁻¹ yeast extract, 10 g·L⁻¹ tryptone, 5 g·L⁻¹ NaCl, 7 g·L⁻¹ potassium phosphate dibasic (K₂HPO₄), 3 g·L⁻¹ potassium phosphate monobasic (KH₂PO₄) containing 100 μg·mL⁻¹ carbenicillin (IBI Scientific, Peosta, IA). BD Bacto brand media components tryptone and yeast extract were obtained from BD Biosciences (San Jose, CA). Cultures were induced with 0.1 mM IPTG (Santa Cruz Biotech, Dallas, TX) at 0.6 OD_{600 nm} and growth continued at 30 °C until harvest. Four hours postinduction, cultures were harvested following previously established protocols.^{33,44} Cells were pelleted by centrifugation (8000g for 15 min) and the resulting pellet was rinsed twice in S30 buffer (10 mM tris acetate pH 8.2, 14 mM magnesium acetate, and 60 mM potassium acetate), and flash-frozen for storage at –80 °C.

To generate crude extracts, cell pellets were thawed on ice and suspended in S30 buffer (0.8 mL per gram cell pellet), and lysed at 20 000 psi (homogenizing pressure) using an EmulsiFlex-B15 homogenizer (Avestin, Ottawa, ON). While all results reported here use high pressure homogenization, cells grown at small scale (50 mL) and lysed by sonication following established protocols⁷⁷ performed similarly (data not shown). Total protein was quantified by Bradford assay with bovine serum albumin (BSA) as the standard using a microplate protocol (Bio-Rad, Hercules, CA). Overexpression of enzymes was confirmed by NuPAGE SDS-PAGE protein gels using Coomassie stain (Life Technologies/Thermo Fisher Scientific, Waltham, MA).

Cell Free Biosynthesis of Mevalonate. Cell free reactions were performed at a volume of 25 μL in 1.5 mL Eppendorf tubes and incubated at 37 °C. The standard reaction contained the following components: 200 mM glucose, acetate salts (8 mM magnesium acetate, 10 mM ammonium acetate, 134 mM potassium acetate), and 10 mM potassium phosphate (K₂HPO₄, pH 7.2).⁴⁶ Unless specified, reactions also included 1 mM NAD⁺, 1 mM ATP, and 1 mM CoA.³³ All reagents and chemicals were purchased from Sigma-Aldrich (St. Louis, MO).

Extract concentration for all CFME reactions was 10 mg·mL⁻¹ total protein. When mixing lysates, the relative levels of each were adjusted to maintain a total protein concentration of 10 mg·mL⁻¹. Reactions were quenched by precipitating proteins using 25 μL of 5% trichloroacetic acid (TCA) and then centrifuging at 15 000g for 10 min at 4 °C. The supernatant was collected and stored at –80 °C until analysis by GC-MS or HPLC.

Lyophilization of CFME Reactions. Cell-free reactions were assembled as described above. Upon mixing, reactions were immediately flash frozen in liquid nitrogen. Lyophilization took place in 25 μL volumes using a VirTis BenchTop Pro

lyophilizer (SP Scientific, Warminster, PA) set to $-86\text{ }^{\circ}\text{C}$ and $<500\text{ mTorr}$ for 16.5 h. To reinstate the CFME reaction, $25\text{ }\mu\text{L}$ of water was added to rehydrate the pellet.

Quantification of Mevalonate, NAD^+ , and Organic Acids. Mevalonate was quantified using an Agilent 7890A Gas Chromatograph with 5977A MSD (Agilent, Santa Clara, CA) based on a method adapted from Dueber *et al.*^{43,78} $10\text{ }\mu\text{L}$ of precipitated reaction supernatant was additionally acidified by $5\text{ }\mu\text{L}$ of 0.5 M HCl to convert mevalonate to mevalonolactone *via* acid-catalyzed esterification. Samples were then extracted *via* mixing with $210\text{ }\mu\text{L}$ ethyl acetate spiked with $50\text{ }\mu\text{g/mL}$ trans-caryophyllene (Sigma), vortexed for 3 min, then centrifuged for at $2000g$ for 3 min using 4445.X microcentrifuge tubes (Neptune Scientific, San Diego, CA). The ethyl acetate fraction was then run on an Agilent HP-5MS ($30\text{ m length} \times 0.25\text{ mm i.d.} \times 0.25\text{ }\mu\text{m film}$) column with helium carrier gas at constant flow of $1\text{ mL}\cdot\text{min}^{-1}$. The inlet temperature was $150\text{ }^{\circ}\text{C}$ and column temperature started at $150\text{ }^{\circ}\text{C}$, increased at $30\text{ }^{\circ}\text{C}/\text{min}$ to $240\text{ }^{\circ}\text{C}$, and was held at $240\text{ }^{\circ}\text{C}$ for 0.5 min. Injection volume was $1\text{ }\mu\text{L}$ with a split ratio of 75:1. Extract ion chromatograms (EIC) for 71.0 m/z and 133.1 m/z were integrated using Agilent MassHunter Quantitation Analysis software. Concentration was determined by comparison to standards prepared by mixing dilutions of (\pm)-mevalonolactone (Sigma) with 152 mM acetate salts, $10\text{ mM K}_2\text{HPO}_4$, and $10\text{ mg}\cdot\text{mL}^{-1}$ of BL21 extract (which contains no expressed proteins with catalytic activity to mevalonate). Standards were quenched with 5% TCA and prepared as described above.

NAD^+ and NADH were quantified using a fluorescent kit (Sigma). Cell free reactions were quenched by diluting 1:200 in the kit extraction buffer and immediately freezing in liquid nitrogen. Samples were then thawed and prepared following the kit protocol.

Glucose, acetate, lactate, pyruvate, succinate, oxaloacetate, phosphate, and ethanol were measured *via* refractive index (RI) using an Agilent 1260 HPLC system (Agilent, Santa Clara, CA). Precipitated sample supernatant was separated isocratically on an Aminex HPX-87H column (Bio-Rad, Hercules, CA) heated to $55\text{ }^{\circ}\text{C}$ with a mobile phase of $5\text{ mM H}_2\text{SO}_4$ and flow rate of $0.6\text{ mL}\cdot\text{min}^{-1}$. Concentration was determined by comparison to standards of known concentration.
